## REVIEW OF MATERIALS REQUIRED FOR "VAN KAMPEN OBSTRUCTIONS"

## SYLVESTER'S THEOREM

$A$ homogenous second degree real polynomial in $n$ variables $X=$ $\left[x_{1}, \ldots, x_{n}\right]$, or equivalently $X A X$. where $A$ is a real ron symmetric matrix, can always be changed to one of following $\binom{n}{t}(n+\xi) / 2$ canonical
forms

$$
x_{1}^{2}+x_{2}^{2}+\ldots+x_{p}^{2}-x_{p+1}^{2}-\ldots-x_{r}^{2}, 0 \leq p \leq r \leq n,
$$

by means of a suitable non-singular linear substitution $X=Y P$, $e-g$ one obtained via the following

ALGORITHM. In case all diagonal terms of $A$ are zero, but say the equal terms at the ( $i, j$ ) and ( $j, i$ ) spots are not, then add $j$ th column and row to the ith column and row, to make double this amount, a nonzero number,
appear at (i,i).
Using this, make rest of th row and column zero. Repeat with smaller matrix obtained by omitting ith row and column. Once new A is diagonal, some interchanges of rows-column pairs, and multiplications of row-column pairs with suitable nonzero scalars, finishes the job.

No two of the above canonical forms are congruent to each other.
If possible suppose that the ( $p, r$ ) canonical form in the $x$ 's becomes a ( $p^{\prime}, r^{\prime}$ ) canonical form in the $y^{\prime} s$ under a nonsingular linear substitution $Y=X P$.

Consider first the last $n-p$, of these substitutional equations $Y=X P$ with the left sides, i.e. the last $n-p$, $y^{\prime} s$, replaced by zeros, and, on the right sides, the first $p x^{\prime} s$ replaced by zeros. If $p$ < $p^{\prime}$, the number $n-p$ of the remaining $x$ 's is more than the number $n-p$ of these equations, and we can find a nontrivial solution for these $n-p x^{\prime} s$.

Now, calculate the first $p^{\prime} y^{\prime} s$, using these values of the $x^{\prime} s$, from the first $p$ of the equations $Y=P X$.

We have thus obtained two $n$-tuples of numbers $X$ and $f$, related by $Y_{0}=X_{0} P$, with the first $p$ coordinates of $X_{0}$ all zero and the remaining not all zero, while the last $n-p$ of the coordinates of $Y_{0}$ are all zero.

This is impossible, because the value of the original quadratic form at $X_{0}$ is negative, and could not have become non-negative, after this Inear substitution, at the corresponding point $Y_{0}$.

Thus $p \geq p^{\prime}, \quad$ likewise $p^{\prime} \leq p$, etc. The invariant $r$ coincides with the rank of $A$, and $p-(r-p)=2 p-r$ is called its signature.
(1) Skewsymmetric forms, i.e. skewsymmetric homogenous degree 2 polynomials in $n$ variables, likewise correspond to skewsymmetric $n$ by $n$ matrices.

By a similar algorithm using symmetrical elementary transformations on rows and columns, we now reach one of the following $[\mathrm{n} / 2]+1$ canonical forms,

$$
\left(x_{1} x_{2}-x_{2} x_{1}\right)+\ldots+\left(x_{2 s-1} x_{2 s}-x_{2 s^{x-1}}\right), \quad 0 \leq 2 s \leq n,
$$

of which no two are congruent. Here 2 s coincides with the rank $r$ of $A$, which is thus now necessarily even.
(2) Bilinear forms in two sets of indeterminates $X=\left[x_{1}, x_{2}, \ldots, x_{n}\right]$ and $Y=\left[y_{1}, y_{2}, \ldots, y_{m}\right]$, are real linear combinations of the products $x_{i} y_{j}$ with coefficients $a_{i j}$. Note that any such bilinear form can be written as XAY, where A is the $n$ by m matrix of coefficients.

In case $n=m$ and $X=Y$, then a bilinear form can be written uniquely as the sum of a symmetric (=quadratic) form and a skewsymmetric form by putting

$$
a_{i j} x_{i} x_{j}+a_{j i} x_{j} x_{i}=1 / 2\left(a_{i j}+a_{j i}\right)\left(x_{i} x_{j}+x_{j} x_{i}\right)+1 / 2\left(a_{i j}-a_{j i}\right)\left(x_{i} x_{j}-x_{j} x_{i}\right)
$$

This corresponds to writing $A=1 / 2\left(A+A^{\prime}\right)+1 / 2\left(A-A^{\prime}\right)$.
But note that even for a bilinear form with $n=m$ and $X=Y$, it may not be possible to simultaneously reduce both its symmetric and skewsymmetric parts to their canonical forms.

In the set of all bilinear forms it is natural to consider the weaker relation of equivalence, i.e. allow all non-singular pairs of inear substitutions $X=P W$ and $Y=Q Z$, with no condition between $P$ and $Q$.

A similar algorithm now leads to one of the following $m i n(n, m)+1$ canonical forms

$$
x_{1} y_{1}+\ldots+x_{r} y_{r}, \quad 0 \leq r \leq \pi n
$$

with no two of these equivalent to each other, where $r=r a n k(A)$.

## WITTEN'S MORSE THEORY

The following remarks pertain only to a very small part of this $k * * \pi$ paper of 1982 , which is difficult but potentially understandable, and also very important :-

For purposes of calculating the Betti numbers of a closed smooth
manifold $M$, we can obviously replace the de Rham derivative $d$ by

$$
d_{t}=e^{-h t} \cdot d \cdot e^{h t}
$$

where $h: M \longrightarrow \mathbb{R}$ is a smooth function, and $t \in \mathbb{R}$. This perturbation is useful because, for $t>0$, or at least for $t$ large, the spectrum of the Hamiltonian (or Laplacian),

$$
H_{t}=d_{t} \cdot d_{t}^{*}+d_{t}^{*} \cdot d_{t},
$$

is easier to understand, provided $h$ is "good".
For example, if $h$ has only a finite number of non-degenerate critical points $p$, where the quadratic form approximating $h$ has eigenvalues $\lambda_{i}$, then in the vicinity of each $p, H_{t}$ is "well-approximated" by the sum of dim(M) one-dimensional havmonic oscillators, each with potential $t^{2} \lambda i_{i}^{2}-$ so with eigenvalues $t\left|\lambda_{i}\right|$ times an odd integer $\geq 1$ - plus dim(M) scalar operators having eigenvalues $+t \lambda_{i}$ or $-t \lambda_{i}$.

Using this (see Henniant for more details) Witten deduces that the number of zero eigenvalues of $H_{t}, t>0$, in dimension $r$, is at most equal to the number of critical points of index $r$, i.e. he obtains a revealing analytical proof of the

Morse inequalities. If smooth function $h: M \longrightarrow$ Th has only iscalated non-degenerate critical points, then the number of such points of index $r$ is at least equal to the $r$-th Betti number of the compact manifold M.

## Comments

(1) Witten's paper is a good entre into physics : see also Atiyah in IHES \# 68.
(2) IHES \# 68 also contains a chatty talk by Bott which is useful to further understand Witten.
(3) Witten in fact gets also the sharp Morse inequalities - i.e. the Smale-Thom chain complex of Milnor's book on h-cobordism - by these analytical means, and much much more: e.g. the degenerate case, when the critical points of $h$ are submanifolds, is also covered. Then, by a somewhat different perturbation of d, he obtains Hopf-type formulae involving fixed points of vector fields, infinitesimal isometries etc. Finally he considers similar problems for some infinite-dimensional manlfolds.
(4) Lawmon in IHES \# 65, in a paper which is un-understandable to us, uses a p-adic version of Witten's perturbation trick to simplify part of Deligne's paper on Weil conjectures

## BANCHOFF'S MORSE THEORY

This paper of 1967 is easy, clear and important.
Consider any linearly embedded cell complex $K \subseteq \mathbb{R}^{N}$ and a linear map $h \mathbb{R}^{N}$ $\longrightarrow \mathbb{R}$ which assiens distinct values to adjacent vertices. It is easy to see that such maps form an open, dense subset 4 of the dual linear space, which, by using the usual metric < , > will be identified with $\mathbb{R}^{N}$ itself.

We put $A(v, \alpha, h)=0$; unless $v$ is the vertex at which the maximum of, $h \mid o$ occurs, when we set $A(v, a, h)=1$. The index of $h$ at a vertex $v$ is now defined by

$$
\text { ind }(v, h)=\sum_{c \in K}(-1)^{d i m c r} A(v, \infty, h) \text {. }
$$

Since multiplying $h$ by a positive scalar does not alter these indices, we can confine ourselves to linear maps $h$ lying in the dense open aubset $u_{K}=U_{K} n S^{N-1}$ of the unit sphere of $\mathbb{R}^{N}$.

Critical Point Theorem If the linear map $h: \mathbb{R}^{N} \longrightarrow \mathbb{R}$ distinguishes adjacent vertices of the embedded cell complex $K \subseteq \mathbb{R}^{N}$, then the Euler characteristic of K is given by

$$
x(K)=\sum_{v} \text { ind }(v, h) \text {. }
$$

The above follows by a simple computation. Next Banchoff defines the curvature, of the linearly embedded cell complex $K$, at its vertex $v$, by averaging the index of $v$ over all $h$, $i$.e. he sets

$$
\operatorname{curv}(v)=s_{h \in u_{K}} \text { ind }(v, h) d S^{N-1} \text {, }
$$

Where $d S^{N-1}$ denotes the usual normalized Lebesgue measure of the unit sphere. So last result implies the

Gauss-Bonnet Formula. The Euler characteristic of an embedded cell complex equals its total curvature, i.e.

$$
x(K)=\sum_{v} \operatorname{curv}(v) .
$$

The following integral, which involves the choice of some euclidean
structure on $A^{\circ}$, the affine span of a closed cell $\alpha$, is easily seen to be independent of the choice of this structure, and is now observed by Banchoff to be an appropriate definition of the exterior angle of the cell of its vertex $v$.

$$
\operatorname{ang}(v, \infty)=s_{h \in u} A(v, o, h) d S^{o} .
$$

As before, the integration is over all those unit vectors h for which the linear map $\langle h, \ldots\rangle: A^{\circ} \longrightarrow \mathbb{R}$ separates the vertices of $o$. If $v$ is not a vertex of or then we'll use ang $(v, \infty)=0$.

Theorema Egregium. The curvature curv(v), of a linearly embedded cell complex $K \in \mathbb{R}^{N}$ at its vertex $v$, satisfies

$$
\operatorname{curv}(v)=\sum_{\alpha \in K}(-1)^{\operatorname{dim}} \text { ang }(v, \infty)
$$

and is thus independent of the embedding.
I.e. the defining integral for ang $(v, \alpha)$ can be replaced by an analogous one over $U_{K} \subseteq s^{N-1}$.

## Comments.

(1) The beauty of the above is that it applies to all cell complexes. In fact Banchoff also gives, on pp. 254-255, a variant of the theory which, at the expense of slightly more involved definitions, even dispenses with the requirement that the linear map $h$ separates adjacent vertices.
(2) When $K$ is an $n$-manifold, then ind $(v, h)$ is ( -1$)^{n}$ times ind $(v,-h)$, from which Banchoff gets another proof of the well known fact that odd dimensional closed manifolds have zero euler characteristic.
(3) The inspiration for Banchoff was Kuiper who had formulated the much more subtle smooth critical point theory into the above format.

## KALAI'S ENUMERATION OF ACYCLIC COMPLEXES

Theorem Let $\mathscr{E}$ denote the class of all k-dimensional simplicial complexes on $N$ ver-tices containing the complete (k-1)-skeleton which have trivial (reduced) homalagy over $\mathbb{Q}$. Then

$$
\sum_{C \in \mathscr{C}}\left|H_{k-1}(C)\right|^{2}=N^{\binom{N-2}{k}}
$$

where $H_{k-1}(C)$ denotes the, necessarily finite, ( $\mathrm{k}-1$ )th integral homology group of $C$.

For $k=1$ we get, because $H_{0}(C)=0$ has cardinality 1 , the formula of Cayley for the number $T(N)$ of trees on $N$ vertices, viz.

$$
T(N)=N^{N-2}
$$

Kalal mentions that his more general theorem resulted by analyzing and generalizing the matrix proof of above given in Biggs and Moon.

Sketch of proof. Let $K$ denote the complete k-dimensional complex on the given $N$ vertices. We assign some total order to the vertices, using this we assign incidence numbers, and shall be interested in the top-most incidence matrix I whose rows are indexed by (k-1)-simplices and columns by $k-s i m p l i c e s$.

The columns of $I$ represent the ( $k-1$ )-dimensional elementary coboundaries of $K$, and it is clear that those stemming from k-simplices containing the first vertex form an integral basis of the column space of 1 . Moreover, the square submatrix of I determined by these columns, and the rows stemming from (k-1)-simplices not containing the first vertex, is evidently a square matrix of size $\binom{N-1}{k}$ and determinant $\pm 1$.

More generally, any of our $\mathbb{Q}$-acyclic $C^{\prime} s$ is determined by a choice of its $\binom{N-1}{k} k$-dimensional simplices, and the square matrix of this aize, determined by the same rows as above, and these columns, has determinant equal to the cardinality of the finite group $H_{k-1}(C)$.

Let Ir be the submatrix of I determined by the aforementioned rows, i.e. those corresponding to ( $k-1$ )-simplices not containing the first vertex. By the Cauchy-Binet theorem, the determinant of the bigeer square matrix $I_{r} \cdot\left(I_{r}\right)^{\prime}$ equals the sum of the squares of the determinants of all these smaller square matrices.
 aforementioned formula.
The binomial duality $\binom{N-2}{k}=\binom{N-2}{N-k-2}$ prompts Kalai to also consider, for any complex $C$ on the given set of vertices, the dual simplicial complex defined by

$$
C^{\star}=\left\{\theta: \theta^{C} \& C\right\} .
$$

Besides $C^{\star *}=C$ etc., he notes also that Alexander duality shows that $C$ is $\mathbb{Q}$-acyclic iff $C^{*}$ is, and that then the finite groups $\frac{H}{K}-1$ ( $C$ ) and $\mathrm{H}_{\mathrm{N}-\mathrm{k}-3}\left(\mathrm{C}^{*}\right)$ are isomorphic.

He ends by explicitly enumerating the $\mathbb{Q}$-acyclic 2 -complexes on 6 vertices, and is especially intrigued by the subclass of $\mathbb{Q}$-acyclic self-dual complexes, i.e. those for which

$$
c^{*}=c
$$

He gives the numbers of the $\mathbb{R} P_{6}^{2}$ 's and other $\mathbb{Q}$-acyclic self-dual 2-complexes which occur on 6 vertices, and poses the problem of finding an enumerating formula for these in general. He refers to Tutte for some such formula for the $k=1$ case.

## Comments.

(1) Kalai also gives a formula for the subclass of $\mathscr{C}$ for which one has prescribed numbers of k-simplices incident to each of the N vertices. Also, using above formula, he checks that "most" Q-acyclic complexes are not $\mathbb{Z}$-acyclic.
(2) For other aspects of self-dual complexes see also papers of Sarkaria, Schild and Bier, as well as of Brehm and Kuhnel.

## THOM'S DIFFERENTIAL FORMS

In his 1975 paper Swan gives this 1957 construction of Thom:
Consider the standard Beometrical realization $K \subset \mathbb{R}^{N}$ where $N=$ number of vertices of $K$. More to the point, consider the associated union $K$ of the affine planes $A_{o}$ determined by the simplices of of $K$.

A differential form on $K$ will then mean a collection of forms wo on these Ao such that we have

$$
\omega_{\theta} \mid A_{\theta}=\omega_{\theta} \text { whenever } \theta \subseteq \sigma .
$$

Here. Thom assumed that each $\omega_{0}$ is smooth and was working over $\mathbb{R}$, while Swan works over $\mathbb{Q}$ and only assumes that these forms have polynomials over $\mathbb{Q}$ as coefficients when we look at them in the obvious local coordinates.

Theorem. Under exterior product, and the de Rham derivative $d$, the aforementioned differential forms on K constitute a graded commutative differential algebra, whose cohomalogy ring coincides with that of $K$ over $\mathbb{R}$ or $\mathbb{Q}$ as the case may be.

## Comments

(1) A different construction of a similar DGA over $\mathbb{Q}$ was given in the interim also by Quillen. Thom was to some extent anticipated by Whitmey Whose book inspired Sullivan too to above result, and also to much much more.
(2) Swan in fact works more generally and defines forms on a semi-simplicial complex.

$$
\text { K: Kumsens } \longrightarrow \text { Yels , }
$$

as all "natural transformations" (i.e. functions $\mathscr{K}(\mathbf{p}) \longrightarrow \Omega(p)$ obeying obvious commutativity conditions) from this contravariant functor to

$$
\Omega: \text { Nuasers } \longrightarrow \mathbb{Q} \text {-Madutes, }
$$

Which associates to a natural number p the totality of rational forms on the affine plane $t_{0}+t_{1}+\ldots+t_{p}=1 .$.
(3) Swan mentions as well known the fact that the above theorem does not extend to fields of nonzero characteristics.
(4) It seems that the ordinary simplicial coboundary - which obeys the formula $\omega \longmapsto$ (sum of vertices) $\omega \omega$ - is the symbol of the differential operator $d$. It should be interesting to formulate the above theorem in this form, i.e. one should also go back from the de Rham complex to this symbolic complex, also taking care of products, and prove that an isomorphism of cohomology rings is induced.

## KATCHALSKI-PERLES INEQUALITY

The inequality. If the nerve $N(\mathcal{K})$ of a family $\mathcal{K}$ of $t$ convex subsets of d-dimensional eucilidean space has dimension less than $d+r$, then its face numbers are bounded above as follows:

$$
f_{k-1}(N(K)) \leq \sum_{i=0}^{d}\binom{r}{k-i}\binom{t-r}{i}
$$

This inequality is sharp. In fact it is easy to spot an arrangement of affine subspaces $K$ at which the above upper bound, which was conjectured by Katchalski and Perles, is attained.

The conjecture was established independently, for all complexes satisfying the conclusion of the following key result, by Eckhoff and Kalai .

Wegrer's Theorem. (Kalai's reformulation). N(S) retracts to a simplicial complex of dimension less than dvia a sequence of operations in which one removes open stars of free faces of dimension $\mathrm{d}-1$.

Here by a free face we mean a simplex which is a proper face of a unique maximal simplex of the complex.

Idea of Kalai's proof. Arranging the convex sets $\left\{e_{1}, \ldots, e_{t}\right\}$ in order identify each simplex $o \subseteq\left\{e_{1}, \ldots, e_{t}\right\}$ with the corresponding exterior monomial of the free exterior algebra $A$ over $\mathbb{R}$ generated by these $t$ variables.

Then the left side of the inequality equals the dimension of the vector subspace $L_{k}$ of $A$ spanned by all cardinality $k$ simplices of $N(K)$.

On the other hand the right side interprets, with respect to any basis of $A$ given by exterior monomials in $\left\{f_{1}, \ldots, f_{t}\right\}$, as the number of such degree $k$ monomials which have at least $k-d$ of their constituent $f$ 's in $\left\{f_{1}, \ldots, f_{r}\right\}$.

Thus the inequality would follow if we can choose these $f_{i}$ 's in such a way that $L_{k}$ has trivial intersection with the vector subspace $R_{k}$ of $\Lambda$ consisting of all degree $k$ elements which are annhilated when we take interior product with any degree $k-d$ exterior monomial in $\left(f_{1}, \ldots, f_{r}\right\}$.

This is so e.g. When the f's are related to the e's by an orthogonal t.gt matrix for which all square submatrices, and thus also the exterior powers of these submatrices, are non-singular.

In fact if some non-trivial linear combination $\omega$ of degree $k$ simplices of $N(K)$ were in $R_{k}$, then we would have, for each cardinality $k-d$ subset $T$ of $\{1,2, \ldots, r\}$, an equation $\left\langle e_{\theta}, f_{T} L \omega\right\rangle=0$.

Kalai rules. this out by choosing $\theta$ to be the first degree d free face, of a "Wegner collapsing" of $N(\mathcal{K}$ ), which occurs in $\omega$, for then these equations interpret as saying that the columns of the (k-d)th exterior power of a submatrix are linearly dependent.

## Comments.

(1) There is some "duality" between convex polytopes and arrangements of affine subspaces which we don't understand fully.

For instance, the "dual" of Wegner's theorem is the theorem - of Steimer and Brugesser-Mani - which tells us that the former can be shelled, and the "dual" of the Katchalski-Perles inequality is the upper bound conjecture of Motzkin, which was established by McMullen, and later generalized to all Cohen-Macaulay complexes (e.g. simplicial spheres) by Stanley.
(2) Kalai's proof was important because it led to exterior shifting see reviews below - which enabled him to in fact establish Eckhoff's conjectured characterization of the f-vectors of such d-callapsible complexes. Still later, he was able to show that this characterization holds even for d-Leray complexes, a notion "dual" to that of Cohen-Macaulay complexes.

The "dual" characterization of f-vectors of simplicial polytopes was conjectured by McMullen and proved by Stanley. The McMullen-Stanley characterization remains open for f-vectors of simplicial spheres.

We note also that there is an obvious numerical duality between the inequalities of Eckhoff-Kalai and those of McMullen-Stanley.
(3) Regarding arrangements of affine subspaces, especially the topology of their complements, see also the Goresky-MacPherson book, and

Ziegler-Zivjaljevic 's, and other older, papers. ${ }^{\text {E }}$ Also see literature on oriented matroids: these in turn figure in characteristic classes for embeddability obstructions.

## CATEGORY OF NATURAL NUMBERS

Associating to each ordered pair $p, q$ of natural numbers the $s e t$ of all monotone (i.e. non-decreasing) maps from $\mathbf{p}=(0,1, \ldots, p)$ into $\mathbf{q}=$ ( $0,1, \ldots, q$ ) we get the category Numbers.

A contravariant functor

$$
\mathscr{K}: \text { Numbers } \longrightarrow \text { fels }
$$

is called a (complete) semi-simplicial complex.
Example 1. If $K$ is a simplicial complex, let $K(q)$ be the set of all sequences of vertices of length $q+1$ supported on simplices of $K$, and let KK $\mathbf{p} \rightarrow \mathbf{q}$ ) map such a sequence $\mathbf{q} \longrightarrow \operatorname{vert}(K)$ to the composite $\mathbf{p} \longrightarrow \mathbf{q}$ $\longrightarrow$ vert $(K)$. Note that $K$ can be recovered from this semi-simplicial complex as the set of all supports of these sequences.

Example 2. In case vert(K) is equipped with some total order, one also has the smaller semi-simplicial complex $K_{0}$ consisting of non-decreasing sequences of vertices supported on simplices of $K$.

Structure of a monotone map. Any non-decreasing map $\mu: p \longrightarrow q$ is determined by its critical points $\left\{c_{1}, \ldots, c_{s}\right\} \subseteq p$ (i.e. all c's such that $\mu(c)=\mu(c+1))$ and the subset $\left\{j_{1}, \ldots, j_{t}\right\} \subseteq q$ of jumps (i.e. j's not in the image of $\mu$ ). In fact $\mu$ has the factorization

$$
\mu=j_{t} \cdot \quad \cdot j_{1} \cdot c_{1} \cdot \quad \cdot c_{s},
$$

into injective maps $J$ having a single jump, and surjective maps $c$ having a single critical point.

It is of interest also to consider, on the category of numbers, functors into other categories. For example, each $K$ determines, by taking the free abelian group $C(S)$ generated by each set $S$, a simplicial abelian group, i.e. a contravariant functor

$$
C(X): \text { Numbers } \longrightarrow \text { Afselian. }
$$

This generalizes the notion of a chain complex, for, aniongst the maps of ABellan, which occur as integral linear combinations of maps C(K) ( $\mu$ ), $\mu$ E Numbers, we have in particular the usual boundary

$$
\theta: \mathrm{C}\left(K^{\prime}\right)(\mathbf{p}) \longrightarrow \mathrm{C}(\mathscr{K})(\mathbf{p}-\mathbf{1}),
$$

Which occurs as an alternating sum of the images $\theta_{i}$ of some $j_{i}$ 's.
(1) Originally Eilenberg-Zilber had defined semi-simplicial complexes as $\mathbb{N}$-graded sets, equipped with some degree +1 and degree - 1 operators, obeying a given list of axioms. Their definition was recast into the above neat form by Kan. Now these face and degeneracy operators of Eilenberg-Zilber coincide with the operators $\mathscr{K}(j)$ and $K(c)$.

We prefer to say "semi-simplicial complex" instead of "simplicial set", because the latter will often mean a set of simplices.
(2) A Kan complex is a s.s.c. for which any $n$ n-simplices (i.e. members of $K(n)$ occur as $n$ of the $n+1 n$-faces of some ( $n+1$ )-simplex iff $g$ coincides with some $\theta_{k}$ on their sum.
(3) See May 's book for an exposition of the combinatorial homotopy theory of Kan complexes. In particular, for the singular complex of a topological space, Kan's combinatorial homotopy groups coincide with the usual ones.

## BJORNER-KALAI INEQUALITIES

For any simplicial complex $K$, let $f_{i}(K)$ be the number of its i-dimensional simplices, and $\beta_{i}(K)$ the dimension of its ith reduced homology over some field FF.

This paper is concerned with relations, between these two sequences of numbers, which hold in general for any K. One such relation is provided by the well known Euler-Poincare theorem which tells us that the alternating $\operatorname{sum}\left(f_{0}-\beta_{0}\right)-\left(f_{1}-\beta_{1}\right)+\ldots$ equals 1 .

The authors discovered that the smaller alternating sums,

$$
x_{i}(K)=\left(f_{i+1}-\beta_{i+1}\right)-\left(f_{i+2}-\beta_{i+2}\right)+\ldots, i \geq 0
$$

are also not arbitrary.
Theorem. For any simplicial complex $K$, one can find anather simplicial complex $E$ which has, for each $i \geq 0, x_{i}+\beta_{i}$ simplices in dimension is of which precisely $\beta_{i}$ are maximal simplices.

Thus, by applying the Kruskal-Katona theorem - see below - to the simplicial complex obtained from $E$ by deleting maximal simplices of dimensions less than $i$, one obtains the inequality

$$
\theta_{i}\left(x_{i}+\beta_{i}\right) \leq x_{i-1},
$$

for each $i \geq 1$.

Proof. By Kalai's theorem there is a shifted simplicial complex $\Delta$ (K) having the same face and Betti numbers as K. Let $X$ be the link of its firat vertex.

The required $E$ is obtained from $\Delta(K)$ by deleting the open star of its first vertex, and is thus the disjoint union of $X$ and $\beta_{i}$ maximal simplices in each dimension i.

Since the cone $C(X)$ of $X$ over the first vertex has $f_{r}{ }^{-} \beta_{r}$ simplices in dimension $r$, it follows that

$$
f_{r-1}(X)+f_{r}(X)=f_{r}-\beta_{r}
$$

Taking the alternating sum of these equations over all $r \geq i+1$ we see that $f_{i}(X)=x_{i}$. So $f_{i}(E)=x_{i}+\beta_{i}$. q.e.d.

## Comments.

(1) The Kruskal-Theorem implies also that there are in general no further relations between the sequences $f_{i}$ and $\beta_{i}$.

To see this use the available $\theta_{i}\left(x_{i}+\beta_{i}\right) \leq x_{i-1}+\beta_{i-1}$ and $\theta_{i}\left(x_{i}\right) \leq x_{i-1}$ to find a compressed complex E with face numbers $x_{i}+\beta_{i}$, having a compressed subcomplex $X$ with face numbers $x_{i}$. Adding the cone of $X$ over a new vertex, we obtain a shifted simplicial complex $\Delta$ having face numbers $f_{i}$ and Betti numbers $\beta_{i}$.
(2) For a given f-vector the Betti numbers are maximum at the compressed complex having that f-vector. This result of Sarkaria was obtained independently by Bjorner and Kalai as follows:

As in the above proof it suffices to maximize over shifted complexes $\Delta$ having the given f-vector. For $\Delta$ shifted we obviously have

$$
\beta_{i}=f_{i}\left(\left(S t_{\Delta} 1\right)^{c}\right)-f_{i+1}\left(S t_{\Delta} 1\right) .
$$

But an argument implicit in a paper of Frankl shows that the f-vector of the star of the first vertex is minimum when the shifted complex $\Delta$ is compressed. (In fact this is equivalent to the Kruskal-Katona theorem). This implies the required result.

Sarkaria proved above result without recourse to shliting. His inductive argument uses homology exact sequences. Byrner and Kalai later gave another proof of their inequalities using such an argument. Its advantage is that it applies to a much lareer class than the class of simplicial complexes.
(3) For a compressed complex one has $\boldsymbol{o}_{i}\left(x_{i}+\beta_{i}\right)=x_{i-1}$ for all i $\geq 0$. This follows by an easy calculation and shows that the BG rner-Kalai

Inequalities are sharp.
Any finlte sequence of non-negative integers is the $\beta-s$ equence of some complex, e.e. a bouquet of spheres. But, if we want to find a smallest such complex, then we can solve the above equations downwards to obtain all the $x_{i}^{\prime} s$, and thus all the $f_{i}^{\prime}$ 's. It is easy to check that any complex having the given Betti numbers has at least as many simplices as the compressed complex with this f-vector.
(4) A clutter (or "anti-chain" or "Sperner system") on N vertices is a family of subsets without any proper inclusion relations. (E.g. the set of circults of a matroid.)

A given sequence if non-negative integers is the $\beta$-sequence of some simplicial complex having $\leq N+1$ vertices iff it is the face vector of a clutter on N vertices.

The necessity follows because (with notation of above proof) $E \backslash X$ is a clutter on $N$ vertices. Conversely given a clutter on $N$ vertices we can close it to a simplicial complex E, and then cone the new part $X$ over a new vertex, to get a complex having $\beta$-vector equal to the face vector of the clutter.
(5) The above observation is useful, because commencing with a classic result of Sperner, a complete classification of the f-vectors of clutters has been obtained by Clements and Daykin-Godfrey-Hilton. Thus all this applies to Betti sequences.

For example, for $N$ even, the aforementioned theorem of Sperner says that any clutter on $N$ points has at most $\binom{N}{N / 2}$ members, with maximum attained only at the clutter of all cardinality $N / 2$ subsets.

Using this it follows that for simplicial complexes on $2 \mathrm{n}+3$ vertices the sum of the Betti numbers is maximum at the irreducible Kuratowski complex $a_{n}^{2 n+2}$.

A very similar result holds also when the number of vertices is odd. There is also given a more complicated result for the minimum of the sum of the Betti numbers of complexes having a given f-vector.

## KRUSKAL-KATONA THEOREM

This ubiquitous and multi-faceted result is all-important and has spawned many analogues and generalizations. It is not quite clear what is (are) the most conceptual way(s) of looking at it. So we'll review it from many angles.

Numerical function $\theta_{k}(t)$. This is the number of ( $t-1$ )-dimensional simplice contained in the simplicial complex $t_{k}$ generated by the $t$ lexicographically first k-dimensional simplices with vertices in $\mathbb{N}$.

Theorem A. Any simplicial complex having $t$ simplices of dimension $k$ has at least $\theta_{\mathrm{k}}(\mathrm{t})$ simplices of dimension $\mathrm{k}-1$.

An inductive approach to this reault, innaugarated by Katona, and polished by Eckhoff and Wegner, reduces it to the following result regarding the above numerical function, which is given explicitly by the binomial formula,

$$
\theta_{k}(t)=\binom{a_{k+1}}{k}+\left[\begin{array}{c}
a_{k} \\
k-1
\end{array}\right)+\ldots+\binom{a_{i}}{i-1}
$$

where the $a_{j}$ 's are the natural numbers, decreasing with $j$, such that

$$
t=\binom{a_{k+1}}{k+1}+\binom{a_{k}}{k}+\ldots+\binom{a_{i}}{i}
$$

Theorem B. The above numerical function obeys

$$
\theta_{\mathrm{k}}(s+t) \leq \max \left(\partial_{\mathrm{k}}(s), t\right)+\theta_{\mathrm{k}-1}(\mathrm{t}) \text {. }
$$

Another (order-theoretic) approach focusses on compressed complexes, i.e. simplicial complexes $T$, on some totally ordered set (say $\mathbb{N}$ ), such that if $\sigma \in T$ and $\theta$ is lexicographically less than $o$, then $\theta$ too should be in $T$. It is clear that there is at most one compressed complex with a given face vector. Now the Kruskal-Katona theorem reduces to the following guise.

Theorem B. An integer sequence is the face vector of some simplicial complex iff it is the face vector of some compresised simplical camplex.

Combinatorial shifting. Given any simplicial complex $K$ on $\mathbb{N}$ and numbers $1<j$, denote by $\Delta_{i j}(K)$ the simplicial complex of the same size obtained by replacing $j$ by $i$ whenever possible. This construction found many uses with Erdos and Rado.

If the transpositions (i j) generate the symmetric group of all permutations of the set of vertices of $K$, then, by doing the above operations $\Delta_{i j}$ in any order one gets a shifted complex, i.e. one which is closed with respect to the product partial orders on equicardinal subsets of $\mathbb{N}$.

The class of shifted complexes is bigeer and more interesting than of compressed complex. But, as far as proving Kruskal-Katona is concerned, Frankl showed that one is still left with the job of establishing the following.

Theorem C. Amongst shifted complexes on $\mathbb{N}$ having a given face vector. the compressed complex has the least number of simplices in St (1).

Why not soup-up the above shifting process to a compressing process? Bollobas-Leader do this via some operations $\Delta$ IJ, involving replacement of subset $J$ by the lexicoeraphically smaller I. These operations preserve closure under inclusion, and, when suitably iterated, lead to the compresged complex, thus yielding Theorem B directly.

Comments.
(1) Even the paternity of $K-K$ is many faceted: apparently Schutzenberger, Harper, and probably some others, also independently obtained it.
(2) The inductive numerical approach extends the domain of validity of the K-K inequalitles way beyond simplicial complexes. For more on these abstract complexes - of Lefschetz and others - see below. In fact cubical complexes were considered even by Kruskal himself.

Also, the homological analogue of $K-K$ was proved in this vein by Sarkaria, and likewise Bjorner and Kalai extended their inequalities way beyond simplicial complexes using this approach.
(3) Combinatorial shifting can be replaced by Kalai's more elegant exterior shifting, but still, the aforementioned Frankl residue remains.

An analogy ; inductive approach $\longleftrightarrow$ exact sequence approach in Morse theory while shifting approach $\longleftrightarrow$ Witten approach. However, in our aetting, we don't know how to obtain explicit "models" for complexes other than simplicial ones.
(4) Besides the analogues and generalizations of $K-K$ alluded to above, one also has
the older Macaulay theorem which characterizes face vectors of commutative semi-simplicial complexes,
the characterization of f-vectors of antichains (or "clutters" or "Sperner systems") obtained by Daykin et al.,
the Clements-Lindstrom theorem which subsumed both $K-K$ (i.e. face characterization of the "fermionic", or "anti-commutative semi-simplicial", complexes) and its "bosonic" analogue, i.e. Macaulay's theorem,
the Heawood-Sarkaria inequality for least valences, and so chromatic numbers, of simplicial pseudomanifolds,
the McMullen-Stanley inequalities for convex sipaplicial polytopes, which in "VKO" will be extended to all simplicial spheres,
the Eckhoff-Kalai inequalities for nerves of arrangements of affine subspaces,
and much, much mare !!
In fact Chapter $V$ of VKO could also be called "Kruskal-Katona Theory", but the title chosen, "Heawood Inequalities", is more appropriate from the point of view of embeddability, the point of view taken by both Kempe and Heawood, who, much before K-K-etc, were already looking at some such inequalities.

Furthermore the title is justified because this embeddability viewpoint will be shown in "VKO" to yield a strengthened form of the deepest of these "K-K theorems", viz. the McMullen-Stanley inequalities.

## HEAWOOD'S "MAP-COLOUR THEOREM"

This **** paper of 1889 will be the starting point of our Chapter $V$. We will review its contents, but instead of (geographical) "maps", "divisions", and number of their "contacto", we will speak of graphs (1.e. one-dimensional simplicial complexes), vertices, and their valence.

Theorem A. If a graph with N vertices embeds in $\mathrm{s}^{2}$ then the average valence of its vertices is at most $6-12 / \mathrm{N}$.

Heawood checks only that equality holds provided one can come down to the complete graph on 4 vertices by a sequence of steps in which the star of a vertex is replaced by joining one of its neighbours, already joined to two other neighbours, to all other neighbours.

He recognizes also that this equality is equivalent to Euler's formula for a simplicial 2-sphere.

For the remaining "cases of degeneracy" he simply asserts that valence can be no higher than this number.
Theonem B. More generally, if a graph with $N$ vertices embeds in $\mathrm{M}^{2}$ then the average valence of its vertices is at mast $6(1+\mathrm{k} / \mathrm{N})$ where k depends only on the closed 2 -manifold under consideration.

Again the argument is as above and the troublesome "degenerate cases" get only a passing mention.

Theorem C. Let x denote the smallest integer bigger than $6(1+\mathrm{k} / \mathrm{N})$ for all N , or, for surfaces with positive k , even such that $6(1+k / x+1)<$ $x$. Then the above graph has chromatic number at mast equal to $x$.

For $k$ positive average valence is a decreasing function of $x$, so the weaker condition ensures that $x$ is bigeer than it provided $N$ is bigeer than $x$. This suffices to do the (by now) standard inductive argument.
Theorem D. If a complete graph on y vertices embeds in $\mathrm{M}^{2}$ then we must have $(y-1) \leq 6(1+k / y)$. For the torus this is best possible.

The first part follows at once from Th. B. For the second he exhibits a toral "map" with 7 "divisions" each in "contact" with any other.
E. Heawood asserts that in fact the inequality of Theorem $B$ is best possible for all surfaces with $k \geq 1$ pointing out that argument given is complete
"- apart from the verification figure. which we have indeed given only for the case of ar anchor ring, but for more highly connected sur faces
it will be observed that there are senerally contacts enough and to spare for the above number of divisions each to touch each."
F. Map colour theorem. For $k \geq 1$, the numbers $x$ and $y$ coincide, and this or the next lowest integer is the chromatic number of the surface.

This follows by putting together Theorems $C$ and $E$. He also writes out the (now) famous square root formula for this number.

He treats now the problem in which some prescribed "counties", i.e. unions of some "divisions", are required to have the same color. Obviously this falls into the programe of finding chromatic numbers of 2-dimensional pseudomanifolds and we'll state the results in this language.

Theorem G. If a graph embeds in a pseudomanifald abtained from $s^{2}$ by identifying some disjoint pairs of vertices, then its chromatic number is at mast 12, and moreover this bound is best posisible.

The first part follows because the valence of each vertex (which, up in $S^{2}$ is a pair) is at most 12 . The hard part is the second which he proves by giving the following example "obtained with much difficulty".
H. Example. There is a 24 -vertex planar graph whose vertices can be split into 12 pairs in such a way that any two pairs have neighbourly representatives.

He suggests that the "curious problem" of finding all such graphs might be of interest.

1. Then, "assuming the verification figure", he proves that if one allows each "county" to have at most $r$ "divisions", then the chromatic number is 6 r . And also, with a similar proviso, a square root formula is proved for the analogous problem for surfaces with $k \geq 1$.
J. Five colour theorem. If a graph embeds in $S^{2}$ then its chromatic number is at mast 5 .

The "map"argument given amounts to the (now) standard book proof: delete a 5 -valent star, then join and contract 2 of its neighbours which were not already neighbours, apply induction, etc.
K. Critique of Kempe's proof. He accepts as valid the following points of Kempe's 1879 proof of the Four Color Theorem.
(K1) In a (well) four coloured graph consider a connected component of the subgraph determined by any two colors a and b. The transposition of $a$ and $b$ in such an $a-b$ region yields another four colouring.
(K2) If neighbours $1,2,3,4,5$ have colours r,b,rig.y respectively, with 2,5 in a b-y region, and 2,4 in a b-g region, then 1,4 cannat be in the same r-g region, and neither can 3,5 be in the same r-y region.

So far so good. But now Kempe assumed that a transposition in 1 's g
region and in $3^{\prime \prime} s$ ry region will remove both the reds. Heawood shows by an example that either transposition can prevent the other from being of any avail and so Kempe's assumption was wrong.

Theorem L. If a graph having all valences even embeds in $S^{2}$ then its chromatic number is at mast three.

Heawood ends his paper - which is only 7 pages long ! - by stating the above result, saying that its proof is "not difficult, but it appears to shed no light" on the 4 colour theorem.

Comments.
(1) The best way of doing the proofs of (A) and (B) is via exact homalogy sequences. This overcomes the bothersome "cases of degeneracy" neatly.

Using this method, Sarkaria generalized these square root chromatic bounds to complexes embedding in higher dimensional pseudomanifolds, but only upto codimension 2 valences.
(2) However generalization of (A) exists even upto tng middle-dimensional valences. This key result will be proved in our book using Van Kampen Theory, and will in turn extend the McMullen-stanley inequalities to all simplicial spheres.

In fact, Van Kampen Theory will allow us to establish, for all compact polyhedra, such chromatic upper bounds, in terms of the minimal numben of vertices required to triangulate a polyhedron.
(3) The "verification figures" left out by Heawood are now all theresee the book of Ringel - so proof of (E), and thus of the Map Colour Theorem, is complete.

The above took quite a while, but Brehm opines that discovering these explicit minimal simplicial 2-manifolds (like discovering explicit transcendental numbers ?) took so long only because there were too many of them ! !

So there might be hope still of giving a short account of the proof of (E) ?
(4) That would of course still leave onerous tasks like (I)! But it would be interesting anyway to at least look at the Heawood Graph (H) more closely: maybe it relates to some known graph, or to the icosahedron, or $\mathbb{R} P_{6}^{2}$ ?
(5) Regarding (K), there is now the Appel-Haken computer-assisted completion of Kempe's proof. Also note that Kempe theory, i.e. the study of (good) 4-colorings of graphs, has been pursued most by Fisk who has some interesting new results here.

## KALAI'S "DIAMETERS ..."

This **** paper introduces commutative shifting, defined analogously to anticommutative shifting, which Kalai-had used previously to establish Eckhoff's inequalities for face vectors of nerves of affine arrangements. He shows how commutative shifting yields the "dual" McMullen's inequalities for face vectors of simplicial polytopes.

This insightful reformulation of Stanley's proof then leads him on to establish (more general) higher codimensional Heawood inequalities for simplicial complexes embedded convexly in euclidean spaces.
(A) Generic monomial bases. The commutative algebra A generated by vertices over $\mathbb{C}$ is the linear span of the set $M$ of all commutative monomials in the vertices. Using a generic (same definition as before) graded algebra automorphism $X$ of $A$, we replace its vector space basis $M$ by a new basis X(M).

If $K$ is a simplicial complex on these vertices, $M(K)$ will denote monomials supported on $K$. Projecting onto the linear span $A(K)$ of $M(K)$, $X(M)$ becomes a spanning set of this subspace. We use any total order, of the vertices $v$, and thus of the letters $x=X(v)$, to select, from this spanning set, the lexicographically smallest basis $\Delta(M(K))$ of $A(K)$.

Correction. Kalai's definition of $<_{p}$ should be only for monomials of game degree, i.e. this is the product partial order, so as before we get the following.
(B) $\Delta(M(K))$ is a shifted order ideal of monomials.

Let us say that a monomial of degree $r$ is a pushout if it contains no letter less than the rth. These arise from degree r simplices, i.e. monomials without repeated letters, by pushing out their letters rif $\ell$, ... steps to the right, thus e.g.

$$
x_{1} x_{3} x_{4} x_{7} \longmapsto x_{4} x_{5} x_{5} x_{7} \quad, \quad x_{4} x_{6} x_{7} \longmapsto x_{6} x_{7} x_{7}
$$

It follows from (B) that the subset of all simplices of $\Delta(M(K))$ is a ahifted simplicial complex. However its size is uaually bigeer than that of K, so Kalai concentrates on a shifted subcomplex of this which he defines as follows.
(C) Structure theorem. The simplices whose pushouts are in $\Delta(M(K))$ constitute a shifted simplicial complex $\Delta(K) \subset \Delta(M(K))$ which has the same size as K. Furthermore, a monomial is in $\Delta(M(K))$ if and only if it is the product of some degree F pushout of $\Delta(M(K))$ and some monomial in the first $r$ letters.

Note that the subset $P(K) \subset \Delta(M(K)$ ) of pushouts is a (non-shifted) order ideal of monomials.

Regarding its proof, we know only how to deduce (C) starting from the following weaker statement.
(c) If $\operatorname{deg}^{\prime}(K)=d$, then $\Delta(M(K))$ does not contain any pushout of degree $\mathrm{d}+1$.

Proof of (C) assuming (c). Let degree $K=d$ and let $L$ be the subcomplex of $K$ obtained by removing its degree d simplices.

Clearly $M(L)$ is a subset of $M(K)$ which coincides with it in degrees less than d. Since $\Delta(M(L))$ is also a subset of $\Delta(M(K))$, it follows that it too coincides with it in degrees less than $d$.

Assuming (C) inductively for $L$, its second part shows that the $f_{d-1}(K)$ degree d monomials of $\Delta(M(K))$ which are not in $\Delta(M(L))$ must be pushouts.

Thus, using (c), all new monomials of $\Delta(M(K)$ ) must be some monomial in the first $d$ letters times one of these $f_{d-1}$ degree $d$ pushouts.

We note now that the number of degree $k$ monomials in $M(K) \mid M(L)$ equals $f_{d-1}(K)$ times $\binom{k-1}{d}$, the number of degree $k$ monomials in which all $d$ given variables ( $=$ the vertices of any degree d simplex) occur.

Omitting an occurence of each of the d variables we see that this factor also coincides with the number of degree $k$-d monomials in which some on all of deiven variables ( $=$ the first d letters) occur.

Thus monomials obtained by multiplying monomials in the first d letters with the $f_{d-1}(K)$ pushouts of $\Delta(M(K))$ are all in $\Delta(M(K)$ ). q.e.d.

Correction. Lemma (6.3) (= Theorem (C) without "only if") is not proved completely in paper because Kalai's (more complicated) argument also assumes (c). As far as (c)'s proof goes, we see from the binomial identity,

$$
\left[\begin{array}{l}
N \\
1
\end{array}\right]\left[\begin{array}{l}
d \\
0
\end{array}\right]+\left(\begin{array}{l}
N \\
2
\end{array}\right]\left[\begin{array}{l}
d \\
1
\end{array}\right]+\ldots+\left[\begin{array}{l}
N \\
d
\end{array}\right]\left[\begin{array}{c}
d \\
d-1
\end{array}\right]=\left[\begin{array}{l}
N+d \\
N-d
\end{array}\right]-\left[\begin{array}{c}
N \\
N-1-d
\end{array}\right),
$$

that the number of degree $d+1$ monomials in $M(K)$, is at most equal to the number of degree $d+1$ monomials on the $N$ letters which are not pushouts. Also, these generic non-pushouts are obviously lexicographically initial. What is not clear to us is why the projections of these monomials constitute a spanning set of the degree d+1 summand of $L(M(K))$ ?? If this could be argued out - it would suffice to deal with the maximal case when $K$ consists of all simplices of degrees d or less then it would follow at once that the degree $d+1$ monomials of $\Delta(M(K))$ are all non-pushouts.

Before looking at how Kalai uses his $\Delta(K)$, we will first go over his reformulation of Stanley's proof of McMullen's g-conjecture.

Shifted order ideals $H(K), G(K)$. For any $K$ with deg(K) $=d$ we will denote by $H(K)$, resp. $G(K)$, the subset of $\Delta(M(K))$ consisting of all monomials whose letters are all bigeer than the $d t h$, resp. ( $d+1$ )th.

From above it follows that these shifted order ideals are finite.
Recall that a degree d simplicial complex $K$ is calledCohen-Macaulay iff link Lk $\mathrm{K}^{\sigma}$ of each simplex of $K$ has trivial reduced homology in degrees less than d-deg( $\alpha$ ).
(D) Reisner's theorem (Kalai's formulation). If K is Cohen-Macaulay, then one can choose $\Delta(M(K))$ so that a monomial lies in it iff it is a monomial of $H(K)$ times some monomial in the first detters.
[We recall that this required some local cohomology arguments: the first d letters of such a generic basis form a so-called homogenous system of parameters for the ring $L(M(K))$.]

So, for a C-M K, one can calculate the face vector of $H(K)$ in terms of the face vector of $K$. This turns out to be the h-vector of $K$. Thus, for a C-M K, its $h$-vector, being the face vector of an order ideal, must obey Macaulay's inequalities.
(E) Stanley's theorem (Kalai's formulation). If K bounds a d-polytope. then one can also ensure that multiplications by powers of the $(d+1)$ th letter yield bijections $H_{i}(K) \cong H_{d-i}(K)$ for all $i \leq d / 2$.
[We recall that this required the deep hard Lefschetz theorem for toric varieties which tells us that, for any toric variety stemming from a polytope, its cohomology, which has the same dimensions as $|H(K)|$, obeys a strong Poincare duality, analogous to that of smooth Kaehler manifolds: the $(d+1)$ th letter corresponds to the Kaehler form, and the primitive classes correspond to $G(K)$.

So, for a polytopal boundary $K$, the face vector of $G(K)$ can be calculated in terms of the face vector of $K$. This turns out to be the g-vector of $K$. Thus, $G$ being an order ideal, it follows that the g-vector of a polytopal boundary obeys Macaulay's inequalities.

Now Kalai makes very good use of (D) and (E) to obtain the following atriking result.
(F) Convex embeddability theorem. If K occur's within the boundary of a simplicial d-polytope with $N$ vertices, then $\Delta(K)$ is a subcomplex of $\Delta(C(d, N))$, where $C(d, N)$ denotes the cyclic polytope on $N$ vertices. Furthermare, one has equatity $\Delta(K)=\Delta(C(d, N))$ iff $K$ is the boundary of a neighbourly d-polytope on N vertices.

Proof. Since shifting preserves inclusions it suffices to consider the case $\mathrm{K}=$ polytopal boundary.

Using (D), we associate to each of the $h_{k}(K)$ degree $k$ monomials of $H(K)$ a disjoint set of simplices of $\Delta(K)$ of degree $i, k \leq i \leq d$, as follows: first take the degree $k$ simplex having such a monomial as pushout, and then add to it any $i-k$ of the first $d-k$ letters.

The total number of i-simplices made this way being $f_{i}(K)$, it follows that the above is in fact a new description of all of $\Delta(K)$. In particular we see that $\Delta(K)$ is dimensionally pure, its top-dimensional simplices being given explicitly as above with i=d.

But we also have (E), which tells us that each monomial of $H(K)$ is some power of the $(d+1)$ th letter times a monomial of $G(K)$ of degree $\leq d / 2$. Combining this fact with the above explicit description of the top simplices, it follows that these are all admissible. By this is meant that if the (k-1)th letter is outside the degree d simplex, then all letters $k$ through ( $d-k+3$ )rd are inside the simplex. Thus it remains only to check the following.
$\Delta(\mathrm{C}(\mathrm{d}, \mathrm{N})$ - and mare generally the commutative shift $\Delta(\mathrm{K})$ of any neighbour-ly d-polytopal boundary on $N$ vertices - coincides with the shifted simplicial complex generated by all admissible degree d simplices on $N$ vertices.

Since the first complex is, by above, a subset of the latterthis follows by checking that the two complexes have the same size. qe.d.
(f) A higher codimensional Heawood inequality. If $\mathrm{K}^{\mathrm{n}}$ occurs within the boundary of a simplicial $(2 n+1)$-polytope, then we must have

$$
f_{n}(K)<(n+2) \cdot f_{n-1}(K)
$$

Proof. Otherwise $\Delta(K)$ being shifted it would contain the n-skeleton of a $(2 n+2)$-simplex. The same would be true for $\Delta(L)$ where $L$ is the ambient polytopal boundary. But from this it is easy to check that some top simplex of $\Delta(L)$ is non-admissible, a contradiction. q.e.d.

## Comments

(1) Theorem (E) for simplicial spheres requires other ideas because now one can't attach a toric variety and use its Hodge theory. Likewise (F) and (f) are true even when $K$ embeds topologically in requisite dimensional sphere or euclidean space but require new methods.
(2) The purely combinatorial regults given in the paper from page 18 onwards apply to any shifting operation $\Delta(K)$ with the above behaviour, so conjecturally to anticommutative shifting also.
(3) This information is then used to study the diameter problem for the dual simple polytopes. Recall that their graph determines their lattice structure. The optimistic conjecture of Hirsch is that a simple d-polytope with $N$ facets has diameter $\leq N$ - d. Kalai gets good bounds for the diameter of dual-to-neighbourly polytopes by using (F).
(4) This last deduction proceeds via showing that such a graph is a magnifier of appropriate order, i.e. that any vertex set of cardinality $\leq N / 2$ always has an appropriate percentage of its neighbours outside it.
(5) He gives references for the curious connections which exist between
the spectrum of the Laplacian matrix of a graph, i.e. incidence matrix times its conjugate, and the magnification of the graph.

## VAN KAMPEN'S "KOMPLEXE ..."

VKO will include a translation of this **** paper of 1932.
(A) Theorem. The space of linear embeddings $K^{n} \longrightarrow \mathbb{R}^{m}$, mi $2 n+2$, is path connected.

Proof. Any direction not parallel to the, at most ( $2 n+1$ )-dimensional, and finitely many, affine subspaces determined by pairs of simplices of an embedded $K$, will be called non-forbidden.

Given two linear embeddings of $K$, and a vertex $v$ of $K$, we join its two images $P_{1}, P_{2}$ to a third point $Q$ such that $P_{1} Q$ and $P_{2} Q$ are non-forbidden with respect to the two embeddings.

We can find a family of linear embeddings containing the first - and likewise another family containing the second - embedding, which keeps the antistar of $v$ fixed, and under which $v$ travels from its initial position to $Q$. To do this extend $P_{1} Q$ to $P_{1}{ }^{\prime} P_{1} Q Q$ ' and, move the star as per $P_{1} P_{1} \longmapsto P_{1}$ ' $Q, P_{1} Q^{\prime} \longmapsto Q Q^{\prime}$. q.e.d.
(B) Whitney trick. If $\mathrm{n} \geq 3$, and a general pasition p.l. map of $K^{\mathrm{n}}$ in $\mathbb{R}^{2 \mathrm{n}}$ has a pair of double points, having intersection numbers +1 and -1 , and belonging to the same pair of n -faces of K , then they can be removed without intraducing any new singularities.

To start with, Van Kampen stated this without any intersection number condition. He joins the two double points by an arc, in just one of the faces, and tries to cone away its tubular boundary out of harm's way. Brown pointed out to him that this does not work: see "Berichtigung", where Van Kampen also states that the intersection number condition is needed, but can't give a proof of the above. Ten years later, Whitney gave a method of removing such a double point pair which used a smooth structure. However it is true that a more elaborate coning argument also works.
(C) More coning. Also, in above situation, we can remove any double point belonging to the same or adjacent $n$-faces.

In "Berichtigung" Van Kampen gives a correct proof. In fact in this case, as Zeeman and others were to later notice, only a small elaboration of the above erroneous coning argument also works.
(D) Piping. In above situation, and even for $\mathrm{n} \geq 2$, we can, by attaching a long thin pipe to any $n$-face, add extra intersections, all with numbers +1 or else -1 , of this $n$-face with all $n$-faces incident to some other ( $n-1$ )-face.
(E) Van Kampen Obstruction. Let $\mathscr{B}$ be the vector which associates, to any unordered pair of disjoint faces of an $n$-dimensional $k$, their intersection number under a siven general position map into $2 n$-space. If this map is changed, then the new vector can be obtained from the old by a sequence of steps, in each of which one adds +1 , or else always -1 , whenever one member of the pair is incident to a chosen ( $n-1$ )-face.

Using later terminology, this theorem says that the characteristic cohomology class [ $B$ ] depends only on $K$, and that its vanishing is a necessary condition for the p.l. (and, as Van Kampen proves, even for the topological) embeddability of $K$ in $2 n-s p a c e$. Also, using (D), and then ( $B$ ) and (C), he removes all singularities, of any eeneral position

(F) Van Kampen-Wu-Shapiro Theorem. An $n$-complex, $n \geq 3, p . l$. embeds in twice dimensional euclidean space if and only if its characteristic class [8] vanishes.

The latter two authors used Whitney's smooth method to establish (B).
Actually above result holds, by virtue of the contemporaneouskuratowski planarity eriterion, even for $n=1$. For $n=2$ it is possible that this condition may suffice only to ensure topological embeddability ?
(G) Embeddability of manifolds. An $n$-pseudomanifold embeds pieceuise linearly in $2 n-s p a c e$.

This is proved in main paper by checking $B]=0$ for such a $K$, in "Berichtigung" directly by using (C). While doing this direct proof, he also checks that identifications in codimensions $\geq 2$ do not effect embeddabllity in twice-dimensional space.
(H) Van Kampen-Flores Theorem. The $n$-skeleton of a $(2 n+2)$-simplex, and the $(n+1)$-join of 3 points, are $n$-complexes not embeddable in $2 n-s p a c e$.

To see this he checks that for a special g.p. map $\mathscr{B}$ has only one nonzero coordinate, and that one needs to change two coordinates at a time as one proceeds to any cohomologous cocycle.

## PERLES' CONJEGTURE

We will give Kalai's simple proof of the following result, which was conjectured by Perles, and proved first by Blind - Mani.

Theorem. A simple polytope $K$ is determined by its graph $G(K)$.
Proof. (A) and (B) below will show how $K$ can be recovered from $G(K)$.
By an acyclic orientation of a cell complex $K$ we mean a partial ordering of its vertices which has exactly one local maximum on each cell. Its h-vector is defined by setting $h_{i}(K)$ equal to the number of vertices which have exactly i smaller neighbours.
(A) Acyclic orientations of K can be recognized, amongst acyclic orientations of $G(K)$, as those which minimize the sum $\Sigma_{i} 2^{i} \cdot h_{i}(K)$.

For an acyclic orientation of $K$ the above sum in fact equals the total number of nonempty cells of K. This follows because each cell has a unique maximum vertex, and, $K$ being simple, any $t$ smaller neighbours of a vertex determine an incident t-dimensional cell, in which the vertex is a local, and thus the global maximum.

On the other hand, were we to calculate the sum using an acyclic orientation of $G(K)$ which is not an acyclic orientation of $K$, some cell would be counted more than once, and we would get a bigger number.
(B) Graphs $G(o)$ of cells o $\in K$ can be recognized as thase connected, full and regular subgraphs of $G(K)$, whase vertices are initial with respect to some acyclic orientation of $K$.

That all $G(a)$ 's are indeed of this type follows because we can separate the vertices of ofrom the other vertices of $K$ by a hyperplane and totally order the vertices by using a general position transverse direction.

Conversely, if t-regular subgraph $H \subset G$ has these properties, consider the t-dimensional face of our simple $K$ which is determined by the biggest vertex of $H$ and itg $t$ neighbourg in $H$. The biggest vertex of $H$ is a local maximum in o, so must be the biggest vertex of $o$, so all vertices of of mast be in the initial set formed by the vertices of $H$. Thus, $H$ being full, $G(o)$ must be a subgraph of $H$. But, since it too, like H, is t-regular and connected, it follows that $G(\alpha)=H$. q.e.d.

## Comments.

(1) The terminology acyclic orientation stems from the fact that for graphs it amounts to an orientation of its edges not giving rise to any 1-cycle.

There is no los's of generality in warking with acyclic orientations which are total orderings of the vertices. To see this note that any acyclic orientation necessarily total orders the vertices of any cell. thus any total order, which extends this partial ordering of the vertices, is itself an acyclic orientation.

Though all total orderings of the vertices of a cell complex are not acyclic orientations - consider e.g. the ordering 1324 of a square this is clearly so for simplicial complexes.
(2) Does every cell complex have an acyclic orientation ? Though we don't know the general answer, it is so for linear cell complexes, i.e. those which embed linearly in some euclidean space.
[In this context it is worth remembering the following striking facts:
A simple manifold $M^{n}$ embeds linearly in $\mathbb{R}^{n+1}$ only if it is a sphere, and
a simple $\mathbb{C P} P^{2}$ does not embed linearly in any $\left.\mathbb{R}^{N},\right]$
In fact any Banchoff function, i.e. a linear functional separating adjacent vertices, gives a total ordering of the vertices of such a cell complex, which obviously has a unique local maximum on each cell.

It seems likely in fact - only the first part of (B) remains - that above proof will extend to show that any linear simple complex is determined by its graph ?
(3) Simplicity - more exactly the fact that for $t \leq d$ any $t$ edges incident to a vertex belong to a t-cell was important in above proof.

For any $K$ equipped with an acyclic orientation it is useful to consider the in-links Lk_v and out-links Lk_v determined by smaller and bigeer nelghbours of each vertex $v$.

With this notation note that $h_{i}$ is the number of vertices $v$ such that $f_{0}\left(L k_{-} v\right)=i$. It is known that for a simple $K$ the ruector is independent of the chosen acyclic orientation, but in general the f-vector of Lk_v is not determined by its $f_{0}$, and so one should look also at the numbers $f_{j}\left(L k_{-} v\right)$.

For example, the Euler characteristic of an in-link coincides with the definition of the index of a vertex in Banchoff's Morse theory, and thus his index formula reads $x(K)=\Sigma_{\mathrm{v}} x(\mathrm{v})$, where $x(\mathrm{v})=x(\mathrm{Lk} \mathrm{v})$. This follows at once from $f_{j}(K)=\Sigma_{v} f_{j}(v)$, where $f_{j}(v)=f_{j-1}\left(L k_{-} v\right)$.
(4) Simple polytope being determined by their lowermost incidences, the dual simplicial polytopes are determined by their uppermost incidences. Kalal mentions that in fact any lower-half, resp. upper-half, incidence matrix of a simple, resp. simplicial, polytope will do the job. It is natural again to ask whether this stronger result also holds for simplicial/simple manifolds ?

A parallel result of Perles says that the lower half skeleton of $a$ simplicial polytope determines it. This was extended to simplicial manifolds by Dancis.
(5) Some other points:
the directions mentioned in the proof of the first part of "(B) shell the polytope,
graph-theoretic manifold theory - see e.g. Cavicctolli - is close to above,
as is characteristic class theory of Gelfand et al.,
and "order-orientable" triangulations might also fit into this scheme ?

## SQUEEZED SPHERES

We will work with a totally ordered universe $U$ of $N$ letters. A subset $S$ of U will be called contiguous if any letter of $U$ which is between two letters of $S$ is itself in $S$. Also, for any $S \subseteq U$, a maximal contiguous subset of $S$ will be called a component.

We denote by $\mathscr{E}(d)$ the set of those cardinality d+1 subsets of $U$ whose components are of even cardinality or else contain the first letter $x_{1}$ or the last letter $X_{N}$ of $U$.

As we'll see below; the simplices of $\&(d)$ together with all their faces form a d-dimensional sphere $C(d)$. Though these cyclic spheres were discovered in 1911 by Caratheodory, the present description was given much later by Gale.
$A$ subset $K \subseteq \mathscr{C}(d)$ will be called shifted in $\mathscr{E}(d)$, respectively compressed in $\mathscr{(}(d)$, if it is closed with respect to the product partial order, respectively lexicographic total order, of $\mathscr{C}(d)$.
(A) Theorem. If $\mathscr{K}$ is a shifted proper subset of $\mathscr{C}(d)$, then the simplices of $K$ together with all their faces form a d-dimensional shellable ball K.

The compressed case (as well as (B) below) is due to Billera-Lee. Much later Kalai observed that their proof applied even under this shifted hypothesis. Such balls K, respectively their boundaries $\theta K$, were christened squeezed balls, respectively squeezed spheres, by Kalai.

Proof. Kalai knew already that pure shifted complexes K, i.e. those generated by any $\mathscr{K}$ which is shifted in the set of all cardinality d+1 subsets of letters, were shellable. He noticed now that the exact same argument worked even for $\mathcal{K}$ 's shifted in $\mathcal{E}(\mathrm{d})$.

As per the definition of shellabillity of $K$, we need to show that $K$ can be so totally ordered, that each $\sigma \in \mathcal{K}$ shares a face $\theta$ with a preceding simplex of $\mathscr{K}$ only if $\theta$ is a face of a preceding adjacent simplex of $\mathscr{K}$, 1.e. one sharing a degree d face with o.

Such a shelling order is in fact given by any total order which extends the praduct partial order of $6 \mathcal{K}$.

To see this note that, $S K$ being shifted, all combinatorial shifts $\Delta a b(o)$ of $\sigma$, which are in $\varepsilon(d)$, are in $K$. If a face $\theta$ of $o$ is, not in any of these simplices, then it must contain all components of o not containing the first vertex of $U$. The assertion follows because a member of $\mathcal{E}$ (d) containing all these components $i s \geq a$ in the product partial order.

C(d) is a pseudomanifold.
To see this note that any odd component containing
codimension one simplex can have at most one incident top faces are those obtained by lengthening it either way. If it has none, then the incident top faces are obtained by adding the
letters contiguous to the component of $x_{1}$ or $x_{N}$. In either case we have exactly 2 possibilities.

So it follows that $C(d)$ is a sphere and all other $K$ 's are balls properly contained in it. qe.d.
(B) Theorem. The g-vector of a squeezed sphere ok is the face vector of an order ideal of monomials.

We'll sketch the argument only for the more important even case $d+1=2 e$ and that too only when $K \subseteq \ell\langle 2 e\rangle$, the set of those cardinality d 1 of letters whose components are all of even cardinality.
[Note that this subset $\mathscr{C}\langle 2\rangle$ of $\mathscr{C}(\mathrm{d})$ is closed with respect to the product partial order, thus a $\delta \mathcal{K} \subseteq \&<2 e\rangle$ which is shifted in $\ell<2 e\rangle$ is automatically shifted in $8(d)$.

Proof. The sets $8<2 \mathrm{e}\rangle$, and $\{$ monomials of degree $\leq$ in $N-2 e+1$ letters\}, are equinumerous.

An explicit bijection $\alpha$ is obtained if, out of the letters of any or \&̌ $2 e>$ not lying in a maximal contiguous set containing the least vertex of $U$, we keep only the first, third, fifth ... letters, and decrease them by $1,3,5, \ldots$ steps respectively. So for example

$$
x_{2} x_{3} x_{5} x_{6} x_{7} x_{8} \longmapsto x_{1} x_{2} x_{2} \quad \text { and } \quad x_{1} x_{2} x_{5} x_{6} x_{7} x_{8} \longmapsto x_{4} x_{4}
$$

The $\alpha(K)$ just defined is an order ideal of monomials whose face vector coincides with the g-vector of the squeezed sphere $\partial \mathrm{K}$.

Very briefly, $B-L$ verify first that $\alpha(K)$ is an order ideal, and then use the shelling order given above to check that the h-vector of the shellable ball $K$ coincides with the face vector of $\alpha(K)$. The proof is completed by checking that the h-vector of this ball coincides with the g -vector of its boundary $s \mathrm{~K}$. q.e.d.

To complete their celebrated proof of the sufficiency part of McMullen's g-conjecture for simplicial polytopes, Billera-Lee were then essentially left with checking the following.
(C) Theorem. If $K$ is compressed then the sphere $\Delta \mathrm{K}$ is polytopal.

We will look at its proof elsewhere.

## Comments.

(1) Odd degree squeezed balls are not very important because they are just cones of even degree squeezed balls.

Also Kalai observes that each squeezed ball is determined by its bounding squeezed sphere.

Also Kalai observes that each squeezed ball is determined by its bounding squeezed sphere.
(2) Squeezed balls are order-orientable, thus their lower-half skeleton is up on their boundary $2 K$. (Cf. Prop. 5.3 of Kalai's paper.)

Stanley has verified the g-conjecture for all simplicial spheres obeying the conclusion of the above result.
(3) The Hirsch conjecture is true for squeezed spheres.

Lee proved this for the compressed case only, but once again his inductive argument extends easily to squeezed spheres. It only uses the fact that for any of our squeezed balls, both the link and the antistar of the smallest vertex are squeezed balls.
(4) With e fixed, Kalai checks that the log of the number of squeezed (2e-2)-spheres on $N$ vertices is at least of order $N^{e}$ for large $N$.

On the other hand Goodman-Pollack showed that the 10 g of the number of polytopal ( $2 \mathrm{e}-2$ )-spheres is at most of order N.logN for large $N$.
[This uses some bounds of Milnor on sums of Betti numbers of some algebraic varieties. Later Alon generalized the G-P argument to non-simplicial polytopes.]

So most squeezed spheres are non-polytopal.
In fact, even though they bound a shellable ball, it is quite possible that squeezed spheres are mostly non-shellable ? [Pachner showed that any simplicial sphere, having some subdivision in common with a minimal sphere, bounds a shellable ball.]

The asymptotic upper bound for the log of the total number of simplicial (2e-2)-spheres can be computed from Stanley's upper bound theorem, and is about N.logN times Kalai's lower bound given above. It would be interesting to augment the squeezing construction somehow, say by using some knotting perhaps, so as to bridge this gap.

## GOLDSTEIN-TURNER FORMULA

We will deal with a simplicial complex $K$, whose vertices are equipped with a partial order, which restricts to a total order on each simplex. For example, if $k$ is a derived, then it comes with a natural partial order of this type, viz. the inclusion order of the original complex.

Following Steenrod, a face $\theta$ of a simplex o, of any such $K$, will be called a megular face of of, if any of its components not containing the last vertex of $o$, either is odd and contains the first vertex of of or else does not contain this vertex and is even.

Theorem. If $K$ is a mod 2 Euler space then the mod 2 sum of all the
regular faces of simplices of $K$ is a cycle which represents the total Stiefel-Whitney class of K .

In case $K$ is a derived, and is equipped with the natural partial ordering of its vertices, then the above cycle is the sum of all the simplices of K .

This case of the above theorem was conjectured by Stiefel, and proved (unpublished) by Whitney, and later, by Halperin-Toledo and Cheeger.

In fact Goldstein and Turner deduce the above result from this case as follows. Let $K^{\prime} \longrightarrow K$ be the simplicial map which images each vertex of $K^{\prime}$ ( $=$ simplex of $K$ ) to its smallest vertex. Then the induced mod 2 chaln map images the sum of the simplices of $K$, to the mod 2 sum of the regular faces of of the simplices of $K$.

## Comments

(1) The totally ordered set of vertices of each o $\in K$ determines a cyclic sphere, one in each dimension less than that of o. The bigaest of these determines the ordinary mod 2 boundary oo. It might be useful to also define the sum of the top faces of all these spheres as the higher boundary of o ?
(2) It seems e.g. that regular faces of a determine a sequence of squeezed balls, one in each dimension upto that of o, and that these bound the aforementioned cyclic spheres. Thus, by virtue of the fact that the higher boundary of the sum of all the simplices of an Euler space is zero, it follows that the mod 2 sum of the regular faces of all simplices is a cycle.
(3) Steenrod's work came much before that of Gale on cyclic polytopes. His regular faces were used to usher in the steenrod squares of cohomology theory, and there is a well-known formula of Thom for Stiefel-Whitney classes in terms of these operations.
(4) It is possible that the higher boundaries $O_{j}(0)$ of (1) also shed more light on the Kruskal-Katona theorem and function $\theta_{j}(n)$ ?
(5) Goldstein-Turner mention that their result also follows from the work of Banchoff and McCrory.

## KALAI'S "f-VEGTORS"

In this ms. Kalai sketches how the local Cohen-Macaulay property, on the links of a simplicial complex, is equivalent to a vanishing condition on a global cohomology, defined in terms of anticommutative cochains as follows.

For $\Lambda$, the exterior algebra generated by our $N$ vertices $v_{1}, v_{2}, v_{3}, \ldots$ over $\mathbb{F}$, we choose an algebra isomorphism $X: \Lambda \rightarrow \Lambda$ yielding letters $x_{i}=$
$X\left(v_{1}\right)$. We note that, for any simplicial complex $K$, the maps $x_{i}: L(K)$ $\longrightarrow L(K), 1 \leq i \leq r$, defined by $[\omega] \longmapsto\left[x_{i} \sim \omega\right]$, image into the kernel of the map $x_{1} \ldots x_{r}: L(K) \longrightarrow L(K)$ defined by $[\omega] \longmapsto\left[x_{1} \sim \ldots \sim x_{\Gamma} \sim \omega\right]$. The rth iterated cohomology of $K$ with respect to $X$ is defined by

$$
H[r, X](K)=\frac{\operatorname{ker}\left(x_{1} \ldots x_{r}\right)}{\operatorname{Im}\left(x_{1}\right)+\cdots+\operatorname{Im}\left(x_{r}\right)} .
$$

We denote by $\Delta_{X}(K)$ the lexicographically smallest basis contained in the spanning set of $L(K)$ determined by the set of all exterior monomials in the letters.

We recall that this is a simplicial complex which is shifted whenever $X$ is generic. We will denote this exterion shift simply by $\Delta(K)$ because. upto a simplicial isomorphism, it is independent of the generic $X$ chosen.
(A) Theorem Generically $H[r, X](K)$ does not depend on $X$. Moreover this generic rth iterated cohomology $H[r](K)$ of $K$ coincides with that of its exterior shift $\Delta(K)$.

Proof. The argument resembles that of the familiar case $r=1$ :
We check that, in $\Delta_{X}(K)$, the rth iterated cocycles, i.e. things lying in kernel of the map $x_{1} \ldots x_{r}$, appear as words whose augmentation by $x_{1} \ldots x_{r}$ is not in $\Delta_{X}(K)$, and that, out of these, the rith iterated coboundaries, i.e. those lying in the sum of the images of the maps $x_{1}, \ldots, x_{F}$, are those which contain at least one of the first r letters. Thus

$$
\operatorname{dim} H[r, X](K)=\left|\left\{o \in \Delta_{X}(K): o n\left\{x_{1}, \ldots, x_{r}\right\}=0, \quad o u\left\{x_{1}, \ldots, x_{r}\right\} 』 \Delta_{X}(K)\right\}\right| .
$$

From the fact that $\Delta_{X}(K)$ is shifted it follows that $\Delta_{X}\left(\Delta_{X}(K)\right)=\Delta_{X}(K)$.
Using this, the above formula shows that dim $H[r, X](K)=$ dim $H[r, X]\left(\Delta_{X}(K)\right)$, i.e. that $H[r, X](K)$ and $H[r, X]\left(\Delta_{X}(K)\right)$ are isomorphic vector spaces.

Finally, gince $\Delta_{X}(K)$ is independent of the generic $X$, the above also easily implies that $H[r, X](K)$ too is independent of $X$. q.e.d.

Besides generic $X$ 's, it is useful also to consider those whose letters are only in general position with respect to the vertices, i.e. are such that the linear expansion of each lexlcographlcally flrst word $x_{1} x_{2} x_{3}$.. $x_{r}$ contains all degree $r$ simplices.

For example, when the first letter of such an $X$ is the sum of all the $N$
vertices, $H[1, X](K)$ coincides with the reduced ordinary cohomology $H(K)$ of K. However it follows easily that this is isomorphic to the generic H[1](K). Thus (A) generalizes Kalai's previous result that exterior shifting preserves cohomomology.
(B) Theorem A degree d simplicial complex K is Cohen-Macaulay if and only if the generic iterated cahomology groups $H^{k}[d-k](K)$ vanish for all $\mathrm{k} \geq 0$.

The following is the argument of "only if" sketched in the paper. Kalai also gives a more detailed separate proof of this implication for the special case when $K$ is shellable. He gives no proof for "if".

In the very special case when $K$ is shifted, shellability is equivalent to the Cohen-Macaulay property, or even to the purity of K. Now both implications follow trivially from the above explicit description of the iterated cohomology of shifted complexes.

Proof of "only if". The iterated cohomologies were not defined as homologies of chain complex, so it is more convenient to look at the associated iterated cohomologies $\underline{H}^{k}[t](K)$, i.e. the homologies of the following chain complexes:

$$
\frac{L(K)}{\operatorname{ker}\left(x_{1} \cdots x_{t-1}\right)} \xrightarrow{x_{t}} \frac{L(K)}{\operatorname{ker}\left(x_{1} \cdots x_{t-1}\right)}
$$

(B1) $H^{k}[\mathrm{~d}-\mathrm{k}](\mathrm{K})$ vanishes iff $\underline{H}^{k}[\mathrm{t}](\mathrm{K})$ vanishes for all $\mathrm{t} \leq \mathrm{d}-\mathrm{k}$
Thls follows very easily from the above definition. Usine now the standard machinery of exact homology sequences Kalai checks the following.
(B2) If all proper links of a degree d simplicial complex K are Cohen-Macaulay, then the cohamalagy $\underline{H}^{k}[t](K), t \leq d-k$, is unaffected by stellar subdivistons.
(B3) In fact this subativision-invariant cohomalogy $\underline{H}^{k}[t](K)$, $t \leq d-k$, identifies with the ordinary cohomalogy $\mathrm{H}^{\mathrm{k}}(\mathrm{K})$ of K .

This last step of proof is accomplished by imitating a well-known argument which identifies de Rham cohomology with ordinary cohomology:

For each vertex $v$ of $K$, let $K_{V}$ denote its closed star in the derived $K^{\prime}$. Then $\left\{K_{v}\right\}$ is an acyclic cover, because the dual cells $n_{v}\left(K_{v}\right)$ have trivial iterated cohomology by the given condition on proper links. So, by imitating the aforementioned, the iterated cohomology of $K$, coincides with the ordinary cohomology of the merve of this cover, which is isomorphic to K. q.e.d.
(C) Theorem. If K is Cohen-Macaulay, then its exter-ior shift $\Delta(\mathrm{K})$ is pure.

Thla is an immediate corollary of Theorems(A) and (B). Note that this is the anti-commutative analogue of Reisner's theorem which is equivalent to saying that the commutative shift of a Cohen-Macaulay $K$ is pure. However the current proof of this analogue is quite different and employs some algebraic geometry machinery of Grothendieck.

The next result too has a known, but only partial, commutative analogue, viz. for polytopal spheres only, whose proof too is quite different, and employs the hard-Lefchetz theorem of toric varieties.
(D) Theorem. The exterior shift $\Delta(K)$, of any $K$ with $N$ vertices contained in a degree d sphere, is contained in the exterior shift of the cyclic sphere of degree d with N vertices.

Kalai's attempted Proof. Recall that the kth letter is outside a degree d admissible simplex iff the next $d-2 k+2$ letters are all inside it. Such simplices determine a shifted simplicial complex $A(d, N)$ of the same size as the cyclic degree d sphere on $N$ vertices.

So the result will follow from $\Delta(K) \subseteq A(d, N)$, and moreover we would have shown that $A(d, N)$ is none other than the exterior shift of the cyclic degree $d$ sphere on $N$ vertices.
(D1) If a shifted complex is not contained in $A(d, N)$ then it must contain some Kuratowski complex $T$ of the following kind:

$$
T=\sigma_{r}^{r} \cdot \sigma_{s-1}^{2 s} \text { where } r+2 s=d
$$

This follows easily from the explicit description of $A(d, N)$. Now, since $T_{\star}$ is an antipodal d-dimensional sphere, it follows that its $d$ th van Kampen obstruction is nonzero. Thus the theorem would follow if we could, a la Sarkaria, show the following.
(D2) If $\Delta(K)$ contains the aforementioned $T$, then there is $a \mathbb{Z}_{2}$-cochain map

$$
\mathrm{L}\left(\mathrm{~K}_{\star}\right) \longrightarrow \mathrm{L}\left(\mathrm{~T}_{\star}\right)
$$

which maps 1 to 1.
However the ms. gives no proaf of the above.
Remark. Note here that we cannot expect such a cochain map from $L\left(K_{\star}\right)$ into $L\left(\left(\Delta(K)_{\star}\right)\right.$, because there are planar graphs $K$ whose $\Delta(K)$ is not planar. (D2) asserts in particular that all such $\Delta(K)$ 's must always contain the ( 3,3 )-Kuratowsi eraph, never the complete eraph $T$ on 5 vertices. Incidentally there are also non-planar graphs $K$ with $\Delta(K)$ planar, which shows that we cannot have a cochain map of above kind from $\mathrm{L}\left(\left(\Delta(K)_{\star}\right)\right.$ to $L\left(K_{\star}\right)$ either.

Even $\Delta\left(K_{\star}\right) \geqslant T_{\star}$ was left open. But Kalai was able to establish a
suggestive analogue for the exterior square. $K$ of $K$, i.e. the simplicial complex of all simplices which are unlons of some 2 simplices of $K$.
(D3) $\Delta\left(K_{A}\right) \supseteq(\Delta(K))_{A}$ and more generally $\Delta(K \cap L) \geqslant \Delta(K) \sim \Delta(L)$.
To prove this Kalai used the interesting dual description of $\Delta(K)$, viz. that it consists of the first words in linear expansions of elements of the subspace $L(K)$ of $\Lambda$.

We will give in Chapter V of "VKO" a proof of Theorem (D), which uses a new equivariant shifting. This process is noncommutative, since it is based neither on the anticommutative, nor on the commutative, algebra generated by the vertices, but on another non-eraded-commutative graded algebra defined by using the group action.

## Comments

(1) The dual problems regarding f-vectors of nerves of affine euclidean arrangements had earlier led Kalai to the study of d-Leray complexes, and he had already proved an analogue of Theorem (B) for these. In his first paper however this dual result was only proved under the stronger assumption of a Wegner shellability which all nerves of above type obey.
(2) Using commutative cochains, Bier has defined very simple cohomologies, in terms of which, both the Cohen-Macaulay and Leray properties are equivalent to some vanishing criteria. It would be very nice if we could show, analogously to the above, that commutative shifting preserves these, and then maybe even obtain a simpler proof of Reisner's theorem, and more ?
(3) McMullen's conjecture. For any simplicial degree d sphere, $\left(h_{0}, h_{1} h_{0}, \cdots, h_{\left.[d / 2]^{-h}[d / 2]-1\right)}\right.$ is the face vector of an order ideal of monomials.

Arguments already given by Kalai in "Diameters.." show that the above is a corollary of (C) and (D).

Here the $h_{i}$ 's are coefficients of the h-polynomial, which is obtained, from the face or f-polynomial of the simplicial complex under consideration, by changing $x$ to $x-1, i$, e. one has

$$
\sum h_{k} x^{d-k}=\Sigma f_{k-1}(x-1)^{d-k}
$$

For a ( $d-1$ )-sphere one has the Dehn-Sommerville equations $h_{k}=h_{d-k}$. This is very easy. In fact the equation for $k=0$ is Euler's equation of the sphere, and the others follow very easily from (and indeed are equlvalent to) the fact that simllar Euler's equations hold also for all proper links.
[Kalal notes that the $D-S$ equations also follow, by an induction on $d$ and $k$, from $\sum_{v} h_{k}\left(L_{k} v\right)=(d-k) \cdot h_{k}(K)+(k+1) \cdot h_{k+1}(K)$, which is not
hard to check directly.]

Thus, by (C) and (D), McMullen's conjecture would follow if we could verify the same assertion for any pure and shifted subcomplex of $A(d, N)$ Which obeys the Dehn-Sommerville equations.

This had been already done by Kalai in his "Diameters..". He gives a more elegant version of this argument in this ms.. explicitly constructing the required order ideal of such a shifted complex.
(4) Besides the duality (both of results and methods) between polytopes and arrangements (egg. the dual of McMullen's conjecture is that of Eckhoff's) we have the uncanny parallelism (of results, not of methods) between commutative and anticommutative shifting. It is possible that perhaps any irreducible representation of the symmetric group likewise determines a useful shifting process? Also, there should be a uniform method, maybe involving de Rham theory or cohomology theory of algebras, which can be applied in every case ?
(A) If a simplicial 2-sphere's vertices are all of the same degree. then it must be isomorphic to the 4 -vertex tetrahedron $S_{4}^{2}$ or the 8 -vertex octahedron $S_{8}^{2}$ or else the 12 -vertex icosahedron $s_{12}^{2}$

This was known even to Plato, and follows easily from Euler's formula.
The tetrahedron and the octahedron have obvious higher-dimensional analogues, but not so the icosahedron. However its existence is a very fortunate fact, because without the icosahedron, mathematics would have been much poorer. In Chapter IV of "VKO" we'll give many examples based on the icosahedron.
(B) Kuhnel's g-vertex complex projective plane CP ${ }_{9}^{2}$ is an example of "icosahedral ubiquity" because it is a "complexification" of RP $6=$ $S_{12}^{2} / \mathbb{Z}_{2}$, the o-vertex real projective plane, in the following sense:

There is a 12 -vertex complex projective plane, obtained by deriving 3 edges of Kuhnel's 9 -vertex complex projective plane, which has a gimplicial involution, whose fixed-point-set is a subcomplex isomorphic to the 6-vertex real projective plane.

The above, which we don't understand completely, is one of many nice things contained in the paper of Kuhnel-Banchoff.

Not so elegant, or even directly connected with the icosahedron, is Kuhnel's original path to his discovery:

The icosahedron can be constructed from a pentagonal prism, by first deriving its top and bottom faces, and then perturbing it slightly so
two triangles replace each of the rectangular vertical faces. A similar perturbation of the triangular prism gives the octahedron.

Start now with a solid triangular prism with base much bigeger than the top, and derive the top. Then cone the surface, excluding the bottom, to a new vertex, and perturb to make the rectangular prism faces into tetrahedra. Finally add a tetrahedron. This gives Bruckner's neighbourly 8 -vertex 3 -sphere $S_{8}^{3}$.

Kuhnel constructed his CP $_{9}^{2}$ by coning $S_{8}^{3}$ over a $9 t h$ vertex, and then used some permutations of the 9 vertices, forming a group of order 9 , to add more simplices.
(C) CP $_{9}^{2}$ has an orvler 54 sroup of symmetries which acts transitively on the 9 vertices, thus every vertex-link is a Bruckner 3-sphere.

The isotropy aroup of each vertex, i.e. group of symmetries of the Bruckner sphere, is of order 6 , being in fact $\mathbb{Z}_{2} \times \mathbb{Z}_{3}$, and the quotient by this normal suberoup is $\mathbb{Z}_{3} \times \overline{\mathbb{Z}}_{3}$.

That the above procedure yields a manifold with the homotopy type of the complex projective plane is not too hard, and at this point Freedman's classification theorem can be used.

But the above paper also has a geometric argument which exhibits an explicit homeomorphism.
(D) $\mathrm{CP}_{9}^{2}$ is the only/simplicial 9-vertex 4-manifold.

This was checked even before it was verified that this manifold is the complex projective plane. To do this Kuhnel-Lessmann verified that none of the other 3 -spheres led to a 9 -vertex 4 -manifold in the above way. jujhbinity 8 valix
(E) The deleted join of the 2-neigbourly RP ${ }_{6}^{2}$ is a 4-sphere, while that of the 3 -neighbourly $\mathrm{CP}_{9}^{2}$ is a 7 -sphere.

The neighbourliness is obvious, while the sphericity follows from the fact that these are self-dual, or, in Schild,s terminology, "nice" complexes.

Note that (E) implies in particular that $\mathbf{R P}_{6}^{2}$ and $\mathbf{C P}_{9}^{2}$ embed respectively in $\mathbb{R}^{4}$ and $\mathbb{R}^{7}$, and that these dimensions 4 and 7 are the best possible.
(F) The general position linear embedding of $\mathrm{RP}_{6}^{2}$ in $\mathbb{R}^{5}$, resp. of $\mathrm{CP}_{9}^{2}$ in $\mathbb{R}^{8}$, is tight, in the sense that all half-spaces contain a connected, resp. simply connected, part of the complex.

Furthermore the space of secants, i.e. lines meeting the complex in at
least two points, is of dimension less than 5, resp. 8
The second part is essentially equivalent to saying that the deleted joins are of dimensions less than 4 and 8 respectively. Likewise, the first part corresponds to the $2-$ and $3-n e i g h b o u r l i n e s s$ of the complexes.
(G) Smooth versions of above embeddings are also known.

For example, consider the map from $\mathbb{R}^{3}$ to $\mathbb{R}^{6}$ eiven by

$$
(x, y, z) \longmapsto(x x, y y, z z, \sqrt{2}, x y, \sqrt{2}, y z, \sqrt{2}, z x) .
$$

This maps the unit sphere $s^{2}$ of $\mathbb{R}^{3}$ into [the sphere $s^{4}$ obtained by sectioning the unit sphere of $\mathbb{R}^{6}$ by] the affine subspace $\mathbb{R}^{5} \subset \mathbb{R}^{6}$ on which the sum of the frirst three coordinates is 1. Furthermore 2 points of $S^{2}$ have the same image iff they are antipodal points.
This smooth Veronese embedding of $\mathbb{R} P^{2}$ in $\mathbb{R}^{5}$ has to be tight because compact conics are connected. It is known also that its secants form a hypersurface.

The definition of the Veronese embedding of the complex projective plane in 8-space is analogous. These were of course known since long, and Kunper had posed the problem of finding non-smooth embeddings with the same properties vis-d-vis tightness and secants. Possibly it was this question which led Kuhnel to his $\mathrm{CP}_{9}^{2}$ ?
(H) There is an elliptic curve in $\mathbb{C P}{ }^{2}$, i.e. a torus determined by $a$ third degree equation, such that the 9 Veronese images of its 9 inflexion points determine a linear embedding of $\mathrm{CP}_{9}^{2}$ as in (F).

This is harder, but $K-B$ give these 9 inflexion points explicitly. Recall here that an elliptic curve is isomorphic to a torus as a group, the group action of the curve being given by collinearity of 3 points. The inflexion points are precisely the order 3 points in this group, and constitute a $\mathbb{Z}_{3} \times \mathbb{Z}_{3}$.

## Comments

(1) We lack a really conceptual definition of $\mathrm{CP}_{9}^{2}$. The aroup $\mathbb{Z}_{3}$ (or its square) seems important, and of course it is within the 3 -fold join of a 2-simplex, it would be nice if it could have a quick definition as a particular kind of deleted join ... ?
(2) If $K$ is t-neighbourly then any linear map of $K$ in a Euclidean space is t-tight, i.e. any half-space intersects it in a t-connected thing.

An interesting problem here is whether a simplicial manifold $K$ which is t -connected, $\mathrm{t} \leq \mathrm{n} / 2$, can be retriangulated in a t -neighbourly way ?
(3) If dimension of deleted join of $K$ is $\leq s$, then the secant space of any linear embedding of $K$ has dimension $\leq s$. Note this space is made up of van Kampen's "forbidden directions", and by projection along a different direction, $K$ embeds into s-space.

The analobous problem here would roughly be whether a simplicial manifold linearly embeddable in s-space can be retriangulated to make its deleted join of dimension $\leq s$ ?

## SHIFTING AND MATROIDS

Let $T$ be a finite subset of a vector space. Then
(i) M, the family of all linearly independent subsets of $T$, is clased with respect ta $\leqq$ and any such independent set can always be augmented to a bisger one by adeline a suitabie element of anather given bieserindependent subset of $T$
(ii) $H$, the family of all circuits, ie minimal linearly depenclent subsets, of $T$, has no proper $\subseteq$ relations, and if two distinct circuits contain a common element, then their union contains a circuit not containing this element.

Following Whitmey, 1935 , any family $M$, resp. M, of finite subsets of a set $T$, which obeys (i), resp. (ii), is called a matroid. Note that the simplicial complex $M$, and the clutter $M$ determine each other.

Kalai's matroid-theoretical generalization of exterior shifting:
(A) Iterated determinants. Given $N^{2}$ variables $X_{i j}$ with indices $i, j \in$ $\{1,2, \ldots, N\}$, we associate, to any two equicardinal sets o $\theta \leqslant$ $\{1,2, \ldots, N\}$, the determinant

$$
X_{o \theta}=\operatorname{det}\left\{X_{i j}: i \in O, \quad j \in \theta\right\}
$$

Likewise, we associate, to any two (lexicographically ordered) equicardinal families $L, K$ of equicardinal gets, the determinant

$$
X_{L K}=\operatorname{det}\left\{X_{\omega \theta}: \theta \in L, \theta \in K\right\}
$$

Note that these successive determinants are elements of $\mathbb{Z}$ [ $\left.X_{i j}\right]$, the ring of all integral polynomials in the $N^{2}$ variables.
(B) Genewic matroid. To any family $K$, of $t$-subsets of $\{1,2, \ldots, N\}$, we associate the matroid $M(K)$, on the set $T$ of all $t$-subsets of $\{1,2, \ldots, N\}$, whase maximal independent sets are all L's with $\mathrm{X}_{\mathrm{LK}}$ nonzero.
[More generally given any prime $p$ we can postulate $X_{\text {LK }}$ nonzero mod $p$.]

Let $A$ denote the exterior algebra over $F=\mathbb{Q}\left(X_{i j}\right)$ generated by $v_{1}, v_{2}, \ldots, v_{N}$, and $C(K) \subseteq A$, its vector subspace spanned by exterior monomials in the $v_{i}^{\prime} s$ which are supported on $K$.

Then the canonical projections of all the degree $t$ exterior monomials in the letters $x_{i}=\sum_{j} X_{i j} v_{j}$ determine a spanning set of $C(K)$ which we will identify with $T$ in the obvious way.

Clearly the generic matroid $M(K)$ of $K$ coincides with the matroid of all linearly independenţ subsets of the generic spamming set $T \subset C(K)$.
(C) The generic matroid $M(K)$ is symmetric, in the sense each permutation of $\{1,2, \ldots, N\}$ induces a simplicial automorphism of the simplicial complex $M(K)$.

This is clear from the definition of $M(K)$.
(D) Lexicographically minimal basis $\Delta(M)$, of any symmmetric matraid $M$, on the set $T$ of all cardinality $t$-sets of $(1,2, \ldots, N)$, is shifted, i.e. is closed with respect to the procluct partial order of $t-s e t s$.

Here of course "basis" means a maximal independent set and the "lexicographically minimal" basis is obtained by seiving out t-sets depending (in the obvious abstract sense) on lexicographically previous t-gets. It need not be the lexicographically smallest basis.

The above result follows because the shuffle permutation proof generalizes at once to the above abstract situation.
(E) Growth of shifted families. Any shifted family $\Delta$ of cardinality $t-s \in t s$ of $\mathbb{N}$ has only finitely many gerserators, ie minimal siets $S$ whase augmentations by any $t-|S|$ bigger numbers are all in $\triangle$. Thus shifted families have palynomial srowth.

The first part though surprising is very easy and at once gives the formula

$$
\left|\Delta_{N}\right|=\sum_{S}\binom{N-\max (S)}{t-|S|}
$$

where $\Delta_{N}$ is the shifted subfamily of $\Delta$ with all vertices in $\{1,2, \ldots, N\}$, and the summatiom is over this fixed finite set of generators $S$ of $\Delta$. This establishes the second part.
(F) Growth of symmetric matroids. Let $M$ be a symmetric matroid on the
 all $t-s e t s$ of $\{1,2, \ldots, N\}$. Then rank $\left(M_{N}\right)$ is a polynamial function of $N$.

Here "rank" of course means cardinality of any basis of the matroid. The result follows from (E) and (D). But note that in (D) one should use the reverse lexicosraphic order in which $T_{N}$ is an initial set: so
the $\Delta\left(M_{N}\right)$ 's will now arise by restricting a shifted family $\Delta$ of t-sets of $\mathbb{N}$ to $\{1,2, \ldots, N\}$.
(G) Shifting is a projection. If $K$ is already shifted, then $\Delta(K)=$ $\Delta(M(K))=K . \quad \operatorname{So} \Delta(\Delta(K))=\Delta(K)$.

This follows at once from the next result.
(H) Some determinantal identities. If K and L are equicardinal shifted families of t -sets of $\{1,2, \ldots, N)$, with determinant $\mathrm{X}_{\mathrm{LK}}$ nonzero, then we must have $\mathrm{L}=\mathrm{K}$ and

$$
X_{K K}=\prod_{i=1}^{N}\left(X_{i i}\right)\left(\left|S t_{i} K\right|-\left|S t_{i+1} K\right|\right)
$$

Here we use the notation of (A) and $i=\{1,2, \ldots, i\}$. When $K$ consists of all t-sets of $(1,2, \ldots, N)$, then above formula is due to Sylvester.

This result is proved by the interesting device of connecting the generic matrix to the identity matrix by elementary mow aciuman operations. The result is true of course for the identity matrix. Shlfted hypothesis comes in to show that $X_{\text {LK }}$ does'nt change when a row/column is added to another.
(I) Shifted familiess are well-quasi-ordered by inclusion, i.e. in any infinite sequence of finite shifted families of $t$-sets, some family must be contained in some succeecling family.

Kalai observes that this follows immediately from a lemma of Higman.

## Comments

(1) Kalai's paper has lots of additional results and information. For example he gives a complete characterization of the srowth palynamials of symmetric matroids.
(2) The blocker (or Alexander dual a la Bier) of the basis of a matroid is the basis of the dual matroid. Above shifting process is well behaved vis-a-vis this duality.
[Another new word for a known thing is threshold graph: which coincides with shifted sraph. Still another: the compression process in Bollobas , book is combinatorial shiftinge.]
(3) The w.q.o property of shifted complexes might be ugeful for the Kuratowski problem ?
(4) Consider the 3-step heirarchy: vertices, (semi)simplices = ordered sets (sequences) of vertices, hyper(semi)simplices = ordered sets (sequences) of (semi)simplices. Visualizing these hypersemisimplices as joins of their constituent (semi)simplices we thus see that the objects $\mathbf{K}, \mathbf{L}$, in the 4 th step of this heirarchy, i.e. sets of sets of sets of vertices, are also natural seometric abjects.
[However none of the total orders (lexicographic, reverse lexicographic, etc.) on simplices is quite "natural" with respect to the aiven total order on the vertices. On the other hand the product partial order is: so maybe one should think of "hypersimplices" as sets of simplices partially ordered by this, and then, to visualize them, join any two whlch are comparable?]

Shifting theory at $4 t h$ step gets much more exciting: e.g. besides distinctness of gupoets constituent simplices of a hypersimplex fwich dex i.e. the next level of of or or determinants $X_{\text {LK }}$ ] we can also consider their disjointness [now some other quotient of the tensor algebra over $A$, e.g. the star algebra, is required] which leads to deleted joins, etc.
(5) The connections between shifting and the theory of polynomial Identities should also be worth looking into ?
